## Abstract

Social media platforms allow users to express their opinions towards various topics online. Oftentimes, users' opinions are not static, but might be changed over time due to the influences from their neighbors in social networks or updated based on arguments encountered that undermine their beliefs. In this paper, we propose to use a Recurrent Neural Network (RNN) to model each user's posting behaviors on Twitter and incorporate their neighbors' topic-associated context as attention signals using an attention mechanism for user-level stance prediction. Moreover, our proposed model operates in an online setting in that its parameters are continuously updated with the Twitter stream data and can be used to predict user's topic-dependent stance. Detailed evaluation on two Twitter datasets, related to Brexit and US General Election, justifies the superior performance of our neural opinion dynamics model over both static and dynamic alternatives for user-level stance prediction.

themselves in following, commenting on or forwarding others' texts (Wang et al.,  
 2014). This poses several new challenges to the field of opinion mining. Firstly,  
 5 users may not explicitly express their opinions in text. Instead, they could show  
 endorsements of their support of others' opinions through social interactions  
 such as *retweet* on Twitter or clicking on the "*Like*" button on Facebook (Thonet  
 et al., 2017). Secondly, users are not necessarily influenced by all the surrounding  
 10 contexts (Qiu et al., 2015). For example, users tend to ignore those tweets  
 containing topics falling outside of their interests. It is difficult to identify  
 which post a user pays more attention to. Thirdly, users might update their  
 opinions over time. An individual's opinion is an outcome of a combination of  
 their predisposition and the influence from their neighbors over a short period  
 15 of time (Cha et al., 2010).

To tackle the aforementioned challenges, existing literatures have utilized  
 user relations (Thonet et al., 2017), contextual information about topics (Ren  
 et al., 2016; Xing et al., 2017) and temporally-ordered documents (He et al.,  
 2013; De et al., 2016; Chen et al., 2018) for opinion/stance detection. How-  
 20 ever, none of them integrated the three factors of social relations, context and  
 temporality of documents into a unified framework. For example, the SNVDM  
 in (Thonet et al., 2017) improved the performance of VODUM (Thonet et al.,  
 2016) with relationships brought in, whilst they did not consider the temporal  
 order of tweets. Ren et al. (2016) introduced a topic-based context to aggre-  
 25 gate tweets for more accurate prediction and achieved the state of the art, but  
 they ignored to leverage relationships. The dJST proposed in (He et al., 2013)  
 extended JST (Lin and He, 2009) to dynamically detect topic and stance shifts  
 over time on product reviews without considering user relations. Chen et al.  
 (2018) used an attention mechanism (Bahdanau et al., 2014) to weigh the impor-  
 30 tance of a user's present tweet, previously published tweets and their neighbors'  
 tweets and successfully predicted the tweet-level stance. However, they ignored  
 the fact that users' tweets are topic-dependent, hence simply aggregating one's  
 previous tweets and neighbors' tweets for stance prediction may not give good  
 results.

35 In contrast, we assume that a user’s opinion<sup>1</sup> is topic-dependent and is  
 formed based on one’s *a priori* perspective and social influence from their  
 friends. Also, users’ opinions are not static and could change over time. While  
 previous work mostly focused on tweet-level stance prediction, we instead work  
 on user-level stance prediction. Our rationale is that an individual tweet may  
 40 be ambiguous in expressing opinions (e.g., sarcastic tweets), however, user-level  
 stance prediction by considering tweets at the global level would have a smooth-  
 ing effect which will potentially generate more accurate results. Moreover, user-  
 level stance prediction has an advantage that it is able to predict a user’s stance  
 towards a specific topic even though the user did not publish any tweets about  
 45 this topic in the current time window.

We thus propose a Neural Opinion Dynamics (NOD) model built on Recur-  
 rent Neural Networks (RNNs) to capture the three key factors for the prediction  
 of user-level opinion dynamics: the user’s past opinions, the user’s neighborhood  
 opinions and contextual information about topics. In our proposed framework,  
 50 we split temporally-ordered tweets into sequential epochs and capture the rep-  
 resentations of both users’ and their neighbors’ topical contextual information  
 using an attention mechanism. Users’ sequential posting behavior is simulated  
 by a Gated Recurrent Unit (GRU) (Cho et al., 2014) network. We train the  
 model through online learning that data stream is split into epochs temporally  
 55 and the model is updated at each epoch sequentially to allow for the prediction of  
 user-level topic-related stances in the following epoch. Our source code is made  
 available at <https://github.com/somethingx01/TopicalAttentionBrexIt>.

The contributions of this paper are summarized as follows.

- We propose a novel Neural Opinion Dynamics (NOD) model that jointly  
 60 models users’ posts, neighborhood and topical contextual information us-  
 ing an attention mechanism.

---

<sup>1</sup>In our work here, we aim to detect a user’s stance (support, be neutral or go against)  
 towards a certain topic on Twitter and use *opinion* and *stance* interchangeably throughout  
 the paper.

- Unlike previous approaches, a user’s sequential posting behavior is simulated by a GRU, which fully exploits the temporal contextual information for online learning.
- 65 • Experimental results on two Twitter datasets show that the proposed approach outperforms the state-of-the-art approaches and is effective in tracking the user-level opinion dynamics.

The rest of the paper is organized as follows. We first review in Section 2 the three lines of research on incorporating social relations for stance detection, neural networks for stance prediction and stance/opinion dynamics detection using  
70 dynamic approaches. We then present our proposed neural network architecture in Section 3 followed by experimental results in comparison with baselines on two datasets relating to Brexit and US General Election in Section 4. Finally, we conclude the paper and outline directions for future research.

## 75 2. Related Work

Our work is related to three lines of research: incorporating social relations and context for sentiment/stance detection, neural networks for stance detection and stance/opinion dynamics tracking.

### *2.1. Incorporating social relations and context for sentiment/stance detection*

80 Early attempt of using social relations for user-level sentiment detection was made by (Tan et al., 2011) who proposed a probabilistic graphical model in which the observed sentiment labels of users were propagated to users without sentiment labels along the edges in their social network. Hu et al. (2013) observed that connected individuals are more likely to hold similar opinion and  
85 incorporated this as a constraint into a probabilistic optimization model for sentiment classification on microblogs. More recently, Thonet et al. (2017) took the re-tweet and re-tweeted status as the observed variables, which were in turn sampled from viewpoint-specific distributions. They ran the proposed model on two political corpora for topic-specific stance classification.

90      Apart from social networks, contexts such as topics and opinion targets have  
 also been proven useful in stance classification (Vo and Zhang, 2015; Ren et al.,  
 2016; Xing et al., 2017; Tang et al., 2019). The integration of context is typically  
 achieved by the attention mechanism, which was originally proposed in (Mnih  
 et al., 2014), which can be viewed as a selector for the most relevant part of  
 95 the input. For example, in (Ren et al., 2016), hashtags were viewed as topics  
 and attention signals were allocated to neighborhood tweets which share similar  
 hashtags. Neighborhood tweets with higher attention signals contribute more  
 towards the sentiment of the tweet of interest. Ma et al. (2018) considered stance  
 as aspect-associated. For each sentence they computed the aspect representation  
 100 from aspect words and used it together with the sentence representation to  
 generate an aspect-stance vector.

## 2.2. *Neural networks for stance detection*

In recent years, neural networks such as Long-Short Term Memory (LSTM)  
 networks (Hochreiter and Schmidhuber, 1997) and Convolutional Neural Net-  
 105 works (CNNs) have been used widely for stance classification (Wang et al.,  
 2016; Du et al., 2019). In SemEval2016 Task 6 (Detecting Stance in Tweets),  
 the top ranked system (Zarrella and Marsh, 2016) was built based on a transfer  
 learning framework with two RNNs. A similar network architecture was pro-  
 posed in (Baziotis et al., 2017) where an attention layer was added on top of  
 110 the BiLSTM to generalize the hidden states. Chen et al. (2016b) introduced a  
 sentence-level attention to an LSTM-based classifier and demonstrated its ef-  
 fectiveness in user-level stance classification. Yang et al. (2018) incorporated  
 topics for relevant emotion ranking. Some other works considered transferring  
 external sentiment knowledge via sentimental word embeddings (Bandhakavi  
 115 et al., 2017; Li et al., 2017). More recently, Majumder et al. (2018) employed  
 a memory neural network to model the inter-aspect dependency, which showed  
 effectiveness on classifying multi-aspect sentences.

### 2.3. Opinion/Stance Dynamics Tracking

Early work to opinion/stance dynamics tracking utilized variants of topic  
models such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003) or stochastic  
processes. For example, He et al. (2013) proposed the dynamic Joint Sentiment-  
Topic (dJST) model built upon LDA by adding a sentiment layer between the  
topic layer and words and assuming that the Dirichlet prior of the sentiment-  
topic-word distribution in the current epoch is influenced by the statistics col-  
lected in the previous  $n$  epochs. Their approach can track the evolution of  
both topics and topic-associated stances from reviews. Sasaki et al. (2014) com-  
bined Twitter-LDA with a variant of Dynamic-LDA to detect the topic trend  
over time. Dermouche et al. (2014) also modified LDA by additionally adding  
documents’ timestamps as observed variables. Volkova and Van Durme (2015)  
explored an active learning setup for user-level stance classification. De et al.  
(2016) forecast user-level opinion dynamics via stochastic processes based on  
the intuitive idea that opinions are hidden variables conditioned on neighbors’  
shared opinions. Another stochastic influential model was proposed in (Jia et al.,  
2017). More recently, Chen et al. (2016a, 2018) leveraged temporally-ordered  
tweets by introducing an attention layer to weigh the importance of a user’s  
previous tweets, their current tweet and their neighbors’ tweets for tweet-level  
stance prediction. They also used an LSTM layer to capture historical influence  
from past epochs. Tweets in their model were represented by the bag-of-opinion-  
words where opinion words were detected using a sentiment lexicon.

Our proposed model is different from the aforementioned models in the fol-  
lowing aspects: (1) our model considers topical information and generates the  
representations of tweets using an attention mechanism; (2) our model incorpo-  
rates contextual information from neighbors to capture the social influence; (3)  
as opposing to (Chen et al., 2016a, 2018) which applies an attention layer to  
distinguish between a user’s previous tweets and current tweets, we model the  
user’s tweets as a posting sequence which naturally captures the user’s posting  
behavior. As will be shown in the experiments section, our model outperforms  
the existing approaches in stance dynamics tracking.

### 3. Neural Opinion Dynamics (NOD) Model

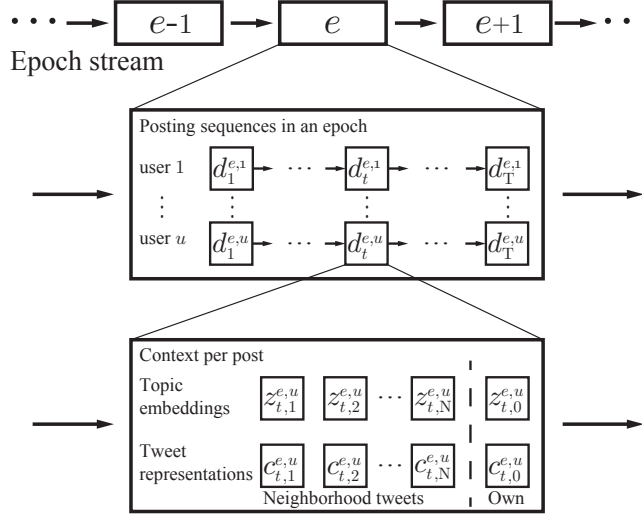

Figure 1: The problem setup for opinion dynamics prediction.

In this section, we present the Neural Opinion Dynamics (NOD) model which leverages content and context information for the tracking of user-level stance dynamics over time. We assume that tweets arrived in a temporal order and can be split into epochs. Each epoch stretches for a fixed window size which can be either time-based (e.g., a day) or count-based (e.g., 10k tweets). In each epoch  $e$ , a user  $u$  posted a sequence of tweets  $\{d_1^{e,u}, d_2^{e,u}, \dots, d_T^{e,u}\}$ . Each tweet  $d_t^{e,u}$  has a tweet representation  $c_{t,0}^{e,u}$  derived from its content and the associated topic embedding  $z_{t,0}^{e,u}$ . We will discuss in Section 3.3 how to generate topic embeddings for tweets. In addition, we assume that when user  $u$  posts a tweet  $d_t^{e,u}$  at epoch  $e$ , their opinion is also influenced by the most recent  $N$  tweets posted by their neighbors in their social network. Therefore, the context information of the tweet  $d_t^{e,u}$  is captured by their neighbors' tweets in the form of a tweet representation sequence  $\{c_{t,1}^{e,u}, c_{t,2}^{e,u}, \dots, c_{t,N}^{e,u}\}$  along with the corresponding topic embeddings  $\{z_{t,1}^{e,u}, z_{t,2}^{e,u}, \dots, z_{t,N}^{e,u}\}$ .

In our problem setup here, the parameters of NOD are updated online, i.e., NOD is updated using the data in the current epoch and is used for predicting

a user’s topic-related stance in the subsequent epoch. By doing so, NOD can be used for tracking the user-level stance dynamics. The problem setup is depicted in Figure 1. In what follows, we first describe the overall architecture of NOD model and then present each of its components in details.

### 3.1. Overall Architecture

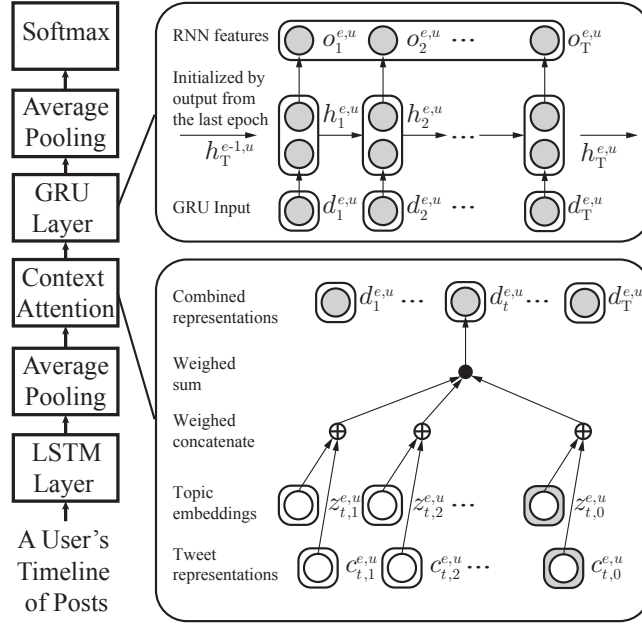

Figure 2: The overall architecture of the proposed Neural Opinion Dynamics (NOD) model.

The overall architecture of the NOD model is shown in Figure 2. Here, the input is a user’s timeline of tweets or posts. An LSTM layer is first used to generate the representation for each tweet. The tweet representation and the corresponding topic embedding is concatenated and subsequently combined with the context information captured by the neighbors’ tweets using an attention mechanism to generate the integrated representation for tweet  $d_t^{e,u}$  posted by user  $u$  at time  $t$  in epoch  $e$ . Each user  $u$  has a sequence of posts  $\{d_1^{e,u}, d_2^{e,u}, \dots, d_T^{e,u}\}$  in epoch  $e$ , which are passed to a GRU layer to obtain the user representation. Finally the user representation is used as features to predict the topic-stance

180 distributions using a Softmax layer. To model the influence of the training data from previous epochs, the last state of the GRU in epoch  $e - 1$  is used to initialize the GRU for the current epoch  $e$ .

### 3.2. Tweet Representation

We generate the representation of a tweet using an extensively exploited 185 LSTM (Sutskever et al., 2014; Tang et al., 2015; Wang et al., 2016; Baziotis et al., 2017), which corresponds to the *LSTM Layer* in Figure 2. LSTM is more effective dealing with language modelling compared with other architectures (Jozefowicz et al., 2015). We use the 300-dimensional word embeddings pre-trained on 20 million tweets (Barbieri et al., 2016)<sup>2</sup>.

Suppose the  $l$ -th word  $w_{t,n_l}^{e,u}$  is mapped into its embedding  $\mathbf{w}_{t,n_l}^{e,u} \in \mathbb{R}^{300}$ , given the previous cell state  $C_{t,n_{l-1}}^{e,u}$ , hidden state  $h_{t,n_{l-1}}^{e,u}$  and the current input word  $\mathbf{w}_{t,n_l}^{e,u}$ , the transition function of the LSTM is calculated as follows:

$$f_{t,n_l}^{e,u} = \sigma(W_f \cdot [h_{t,n_{l-1}}^{e,u}, \mathbf{w}_{t,n_l}^{e,u}] + b_f) \quad (1)$$

$$i_{t,n_l}^{e,u} = \sigma(W_i \cdot [h_{t,n_{l-1}}^{e,u}, \mathbf{w}_{t,n_l}^{e,u}] + b_i) \quad (2)$$

$$o_{t,n_l}^{e,u} = \sigma(W_o \cdot [h_{t,n_{l-1}}^{e,u}, \mathbf{w}_{t,n_l}^{e,u}] + b_o) \quad (3)$$

$$\tilde{C}_{t,n_l}^{e,u} = \tanh(W_C \cdot [h_{t,n_{l-1}}^{e,u}, \mathbf{w}_{t,n_l}^{e,u}] + b_C) \quad (4)$$

$$C_{t,n_l}^{e,u} = f_{t,n_l}^{e,u} \odot C_{t,n_{l-1}}^{e,u} + i_{t,n_l}^{e,u} \odot \tilde{C}_{t,n_l}^{e,u} \quad (5)$$

$$h_{t,n_l}^{e,u} = o_{t,n_l}^{e,u} \odot \tanh(C_{t,n_l}^{e,u}) \quad (6)$$

190 where  $\cdot$  stands for the matrix multiplication and  $\odot$  is an element-wise multiplication operator.  $W$  and  $b$  are the parameters to be trained. The LSTM layer outputs a sequence of hidden states  $\{h_{t,n_1}^{e,u}, h_{t,n_2}^{e,u}, \dots, h_{t,n_L}^{e,u}\}$ , which are conveyed to an average pooling layer to obtain a tweet representation  $c_{t,n}^{e,u}$ .

### 3.3. Topic Embedding Generation

195 The *topic embedding* in Figure 2 captures the topic information of each tweet. The generation of the topic embedding is separated from the learning process.

---

<sup>2</sup>[https://drive.google.com/drive/folders/0B13VF\\_-CUshPd3FqdVJ2c1ZJaXc](https://drive.google.com/drive/folders/0B13VF_-CUshPd3FqdVJ2c1ZJaXc)

We use the Hierarchical LDA (HLDA)<sup>3</sup> for hierarchical topic detection<sup>4</sup>. In HLDA, each document is allocated with a set of topics which is essentially a path from the root to a leaf in a topic tree, where higher level nodes are more general topics. The topic tree is generated using a nested Chinese Restaurant Process (nCRP) (Blei et al., 2010). Each document is generated by drawing words from its assigned topics. For each tweet, we chose its level-2 topic in order to achieve balanced topic granularity. In HLDA, each topic is represented as a distribution over a fixed vocabulary. We sort the vocabulary by word frequency, keeping the normalized first 100 dimensions as the representation for each topic. Finally, each tweet is associated with a topic represented as a vector, which is denoted as  $z$  in Figure 2.

### 3.4. Context Attention

We assume that when a user posts a tweet, they would pay more attention to their neighbors’ tweets carrying topics of their interests. Context-based attention mechanism has been demonstrated effective in a variety of tasks including topic aware response generation (Xing et al., 2017), sentiment analysis (Ren et al., 2016) and geolocation prediction (Miura et al., 2017). In the context attention layer of NOD shown in Figure 2, the input consists of a fixed number of neighborhood tweets  $\{c_{t,1}^{e,u}, c_{t,2}^{e,u}, \dots, c_{t,N}^{e,u}\}$ , their respective topic embeddings  $\{z_{t,1}^{e,u}, z_{t,2}^{e,u}, \dots, z_{t,N}^{e,u}\}$ , the user’s current tweet  $c_{t,0}^{e,u}$  and topic  $z_{t,0}^{e,u}$ . First, for each tweet, its final representation is generated by combining the tweet representation with its corresponding topic embedding by:

$$g_{t,n}^{e,u} = \frac{\alpha_1 z_{t,n}^{e,u} \oplus \alpha_2 c_{t,n}^{e,u}}{\alpha_1 + \alpha_2} \quad (7)$$

where  $\alpha_i$  captures the importance between topic and content. Note that if  $\alpha_1 \ll \alpha_2$  then the model degenerates to the one entirely relying on the textual information. The combined representations are then passed to a user attention layer

<sup>3</sup><http://www.cs.columbia.edu/~blei/downloads/hlda-c.tgz>

<sup>4</sup>We did not use LDA here as it requires pre-setting the topic number while HLDA can automatically infer the topic number from data.

whose output  $d_t^{e,u}$  is a normalized weighed sum of  $\{g_{t,1}^{e,u}, g_{t,2}^{e,u}, \dots, g_{t,N}^{e,u}, g_{t,0}^{e,u}\}$ :

$$d_t^{e,u} = \sum_{n=0}^N \beta_n g_{t,n}^{e,u} \quad (8)$$

$$\beta_n = \frac{\exp(\mathbf{v}^T u_{t,n}^{e,u})}{\sum_{n=0}^N \exp(\mathbf{v}^T u_{t,n}^{e,u})} \quad (9)$$

$$u_{t,n}^{e,u} = \tanh(\mathbf{W} g_{t,n}^{e,u} + \mathbf{b}) \quad (10)$$

where  $\beta_n, (n > 0)$ , represents the user's attention towards  $n$ -th neighborhood tweet. In other words,  $\beta_n$  essentially measures the degree of influence from the  $n$ -th neighborhood tweet and  $\beta_0$  is the attention signal on the user's current tweet.  $\mathbf{v}$  is the weight vector,  $u_{t,n}^{e,u}$  functions as a smoothing factor calculated from  $g_{t,n}^{e,u}$  by a fully connected layer.

### 3.5. User-Level Stance Prediction on Streaming Data

It was previously demonstrated that GRU outperforms LSTM in all tasks except for language modelling (Jozefowicz et al., 2015). As such, we feed the integrated representations of user  $e$ 's post sequence in epoch  $e$ ,  $\{d_1^{e,u}, d_2^{e,u}, \dots, d_T^{e,u}\}$ , to a GRU layer for user-level stance prediction. Let  $h_t^{e,u}$  denote the hidden state, the current state  $h_t^{e,u}$  is updated based upon the previous state  $h_{t-1}^{e,u}$  as follows:

$$s_t^{e,u} = \sigma(W_s \cdot [h_{t-1}^{e,u}, d_t^{e,u}] + b_s) \quad (11)$$

$$r_t^{e,u} = \sigma(W_r \cdot [h_{t-1}^{e,u}, d_t^{e,u}] + b_r) \quad (12)$$

$$\tilde{h}_t^{e,u} = \tanh(W_h \cdot [r_t^{e,u} \odot h_{t-1}^{e,u}, d_t^{e,u}] + b_h) \quad (13)$$

$$h_t^{e,u} = (1 - s_t^{e,u}) \odot h_{t-1}^{e,u} + s_t^{e,u} \odot \tilde{h}_t^{e,u} \quad (14)$$

where  $s_t^{e,u}$  is the update gate,  $r_t^{e,u}$  is the reset gate,  $W_s, W_r, W_h$  are the weight matrices and  $b_s, b_r, b_h$  are the biases. The hidden states are then passed to an average pooling layer to obtain a user representation  $h^{e,u}$ , which is transformed with the following equation:

$$o^{e,u} = W_{\text{out}} \cdot h^{e,u} \quad (15)$$

where  $W_{\text{out}}$  maps the user representation  $h^{e,u}$  into a dimension of  $C$  categories.

The output is normalized by a Softmax layer:

$$y_c^{e,u} = \frac{\exp(o_c^{e,u})}{\sum_{i=1}^C \exp(o_i^{e,u})} \quad (16)$$

which is a distribution over  $C$  categories. The loss function is the KL-divergence (Kullback, 1997) loss described as:

$$\mathcal{L} = \sum_{u=1}^U \sum_{i=1}^C \mathbf{KL}(y_i^{e,u} || g_i^{e,u}) \quad (17)$$

215 where  $g^{e,u}$  is the ground truth distribution over categories. Assuming there are  $K$  topics and each topic has  $S$  stance labels, then there are essentially  $C = K \times S$  categories. We can map the  $C$ -length vector  $y^{e,u}$  into a  $K \times S$  matrix to obtain the topic-stance distribution.

To model the impact from previous epochs, we initialize the state of GRU  
220 for user  $u$  in epoch  $e$  with the final state of GRU for user  $u$  in epoch  $e - 1$ , that is,  $h_0^{e,u} = h_T^{e-1,u}$ . The process is repeated for each epoch and this results in a long RNN transition chain.

### 3.6. A Variant of the Proposed Model

The NOD model described so far outputs topic-associated stance labels for each user. We also perform coarse-level stance classification in which the output is a three-class stance label (*‘oppose’*, *‘neutral’* or *‘support’*) with topics ignored. This is achieved by modifying the output layer and the loss function of NOD. Concretely, the output  $o^{e,u}$  is a 3-dimensional vector and the loss function is changed to cross-entropy loss defined as:

$$\mathcal{L} = - \sum_{u=1}^U \log \left( \frac{\exp(o_{g^{e,u}}^{e,u})}{\sum_{i=1}^3 \exp(o_i^{e,u})} \right) \quad (18)$$

where  $g^{e,u}$  is the ground truth three-class stance label. We call such a variant

225 **NOD\_Coarse.**

## 4. Experiments

### 4.1. Experimental Setup

**Data.** We constructed two datasets by crawling tweets related to Brexit and US General Election 2016 using the Twitter Streaming API with relevant hashtags. For Brexit, tweets were crawled between 2nd and 21st of June 2016 using hash-  
230 tags *#EUPref*, *#EU*, *#Referendum*, *#Brexit*, *#VoteRemain* and *#VoteLeave*. For US General Election, tweets were crawled between November 6th and 7th 2016 using keywords *Trump*, *Clinton* and *Hillary*. Only English tweets were kept and duplicate tweets including re-tweets were removed. Users’ social networks  
235 (*following* and *follower* relations) were also collected. The BREXIT dataset was split into epochs every other day, which resulted in a total of 9 epochs with each epoch consisting of 40,440 tweets on average. The ELECTION dataset contains a total of 452,128 tweets and were split into 11 count-based epochs with the epoch size set to 40,000 and on average 16,019 users per epoch. The statistics  
240 of the two datasets are summarized in Table 1. The distribution of opposed, neutral and supportive users per epoch is shown in Figure 3. It can be observed that the ELECTION dataset has more polarized users compared to the BREXIT dataset.

**Pre-processing.** We pre-process tweets by tokenization, lowercasing, removing  
245 URLs, user handles (@user) and email addresses. Recall that in our model each

Table 1: Statistics of the two Twitter datasets. ‘user/epoch’ is the average number of users per epoch and ‘tweet/user/epoch’ is the averaged number of tweets per user in an epoch.

	BREXIT	ELECTION
#user	38,335	108,689
#tweet	363,961	452,128
#epoch	9	11
user/epoch	10,802	16,019
tweet/epoch	40,440	40,000
tweet/user/epoch	3.7	2.5

Figure 3: The number of opposed, neutral and supportive users versus epochs.

user is a training instance consisting of a sequence of posts. In our experiments, we set each user’s post sequence to a fixed length by either padding null tweets for users with few tweets or trimming extra tweets for users with too many tweets. The same rule was also applied when dealing with a user’s neighborhood context. In our datasets, we observe that less than 11% of the users have posted more than 3 tweets in any epoch. As such, we set the length of a user’s posting sequence in any epoch to 3. We also observe that users on average possess a neighborhood context of 5 tweets in each epoch. Therefore, we set the neighborhood context size to 5 in our experiments. The maximum length of each tweet was set to 24 since over 88% tweets have less than 24 words.

**Topic Setting.** As mentioned before, we used HLDA to extract topics from tweets. As there might be potentially a large variety of topics discussed in tweets, we only kept the most prominent topics and merged topics with fewer than 10,000 associated tweets as ‘Others’. The prominent topics are illustrated in Table 2, where we removed common stop words<sup>5</sup> and manually assigned a

<sup>5</sup><https://github.com/somethingx01/TopicalAttentionBrexit/blob/master/postCommonStopWords.txt>

label to each topic for easy understanding. We further introduced a ‘*Null*’ topic for those null tweets added to the training data. We ended up with 10 topics for the BREXIT data and 9 topics for the ELECTION data.

**Ground Truth Stance Labels.** As it is very difficult to manually annotate  
265 over 800k tweets in our datasets, we resorted to training a stance classifier using distant supervision. In particular, for BREXIT, we collected over 4 million tweets<sup>6</sup> between May 16th and June 2nd 2016 with hashtags clearly indicating stances. Concretely, we assign stance label ‘*support*’ to tweets if they exclusively carry hashtags ‘*#voteleave*, *#euistheproblem*, *#leaveeu*, *#betteroffout*, *#take-*  
270 *control* or *#votebrexit*’, but do not contain ‘*#voteremain*, *#strongertogether*, *#stayintheeu*, *#strongerin*, *#bettertogether* or *#remainineu*’. We annotate opposite tweets vice versa. Tweets without stance-indicative hashtags and do not contain any polarity words are assumed to be ‘*neutral*’. This practice was inspired by the observation that most users use their own hashtags to manifest  
275 their political preferences, when we were manually annotating 1,000 validation tweets in the initial pass. For example, both tweets ‘*#TakeControl on 23rd in #EUref*’ and ‘*Great Britain is happy to trade with its neighbours, it does not need their laws imposed upon #VoteLeave*’ show a ‘*support*’ stance, while tweet  
280 ‘*Gove had enough of experts. Would rather listen to experts as won’t make as many errors as gobby knowalls. #StrongerIn*’ exhibits an ‘*oppose*’ stance. Similarly, for ELECTION, we collected over 17 million tweets in the first week of

---

<sup>6</sup>Only the original tweets were accounted for the user-level ground truth acquisition. Retweets and duplicate tweets were removed.

November 2016 with stance-indicative hashtags such as ‘*#votetrump*, *#trump-willwin*, *#neverhillary*, *#crookedhillary*, *#draintheswamp* and *#notwithher*’ for ‘support’ and ‘*#votehillary*, *#nevertrump*, *#trumptapes*, *#imwithher*, *#vote-blue* and *#trumpdown*’ for ‘oppose’, and sampled neutral tweets in a similar way. We then trained an off-the-shelf stance classifier DataStories<sup>7</sup> (Baziotis et al., 2017), which gave the best result in the SemEval-2017 Task 4 on “Sentiment Analysis in Twitter”, using these external corpora. To assess the accuracy of such externally-trained stance classifier, we manually annotate 1,000 tweets, and report the results in Table 3. Since some studies rely on sentiment lexicons e.g., emoticons, for the acquisition of ground truth labels (Marchetti-Bowick and Chambers, 2012; Lim and Buntine, 2014; Chen et al., 2018), we also compare the results with those obtained using Sentiment140Lex (Mohammad et al., 2013), a lexicon specially designed for Twitter sentiment analysis, and Vader (Gilbert, 2014), a lexicon-based sentiment classifier. It can be observed that DataStories significantly outperforms Sentiment140Lex and Vader by a large margin. This is not surprising since sentiment lexicons are primarily used for sentiment classification, which is, however, quite different from stance prediction since tweets containing positive words could express an ‘*opposing*’ stance. To further obtain the user-level topic-stance distributions, for each user we calculate the number of tweets under each topic with different stance labels and normalize the counts to obtain the topic-stance distributions.

**Baselines.** Recall that in Section 1 we elaborated our motivation by analyzing six related models. Here, we choose SNVDM as a static baseline which incorporates user relationships. CbNNM is chosen considering the utilization of context attention. As the dynamic baselines we employ dJST, SLANT and CSIM.W. We further add DataStories since it has been used for distant supervision. For the methods which can only output tweet-level stance labels, we aggregate the stance classification results by users to obtain the user-level stance labels. dJST (He et al., 2013) is a weakly-supervised LDA-based generative model for

---

<sup>7</sup><https://github.com/cbaziotis/datastories-semeval2017-task4>

dynamic sentiment-topic detection. The model used the sentiment-topic-word statistics gathered in the previous  $n$  epochs to modify the Dirichlet prior for the sentiment-topic-word distribution in the current epoch. We incorporate into the model the word prior polarity information obtained from Sentiment140Lex.

315 SLANT (De et al., 2016) is a supervised probabilistic generative model which models each user’s latent opinions over time as a multidimensional stochastic process. Users’ extant messages and stance labels are considered as observations for parameter estimation.

CSIM\_W (Chen et al., 2018) used an attention layer to weigh the importance of  
320 a given user’s previously published tweets, their current tweet and their neighbors’ tweets and employed an LSTM layer to capture the influence in the previous epochs. They represented each tweet using the bag-of-opinion-words which were identified using Vader (Gilbert, 2014). We also implemented a variant of CSIM\_W, called CSIM\_W\_Rep, in which each tweet is represented by a sequence  
325 of word embeddings as in our model.

SNVDM (Thonet et al., 2017) is an unsupervised LDA-based generative model where the sender/receiver information is regarded as observed variables, which is generated by a hidden viewpoint variable. In our experiments, a user is a sender and their followers are receivers.

330 CbNNM (Ren et al., 2016) considered hashtags as topics. In their model, the contextual information of a tweet (i.e., the neighbors’ tweets sharing the same hashtag) serve as features for tweet-level stance classification.

DataStories (Baziotis et al., 2017) is the state-of-art method in tweet-level stance classification.

335 Among the aforementioned baselines, dJST, SLANT, CSIM\_W and CSIM\_W\_Rep are dynamic models whose parameters are updated with the continuously arriving data. The static models such as SNVDM, CbNNM and DataStories are trained from the data in the current epoch and used to predict the stance labels of tweets in the next epoch. Also, dJST and SNVDM are unsupervised models  
340 that do not use any tweet label for training.

## 4.2. Results

We evaluate the performance of various models in terms of accuracy and micro-F1 for coarse-grained (i.e., three-class) stance classification. For NOD, the output topic-stance distributions are aggregated across topics to obtain the user-level stance labels. For NOD\_Coarse, the output is already one of the three stance classes.

### 4.2.1. Brexit

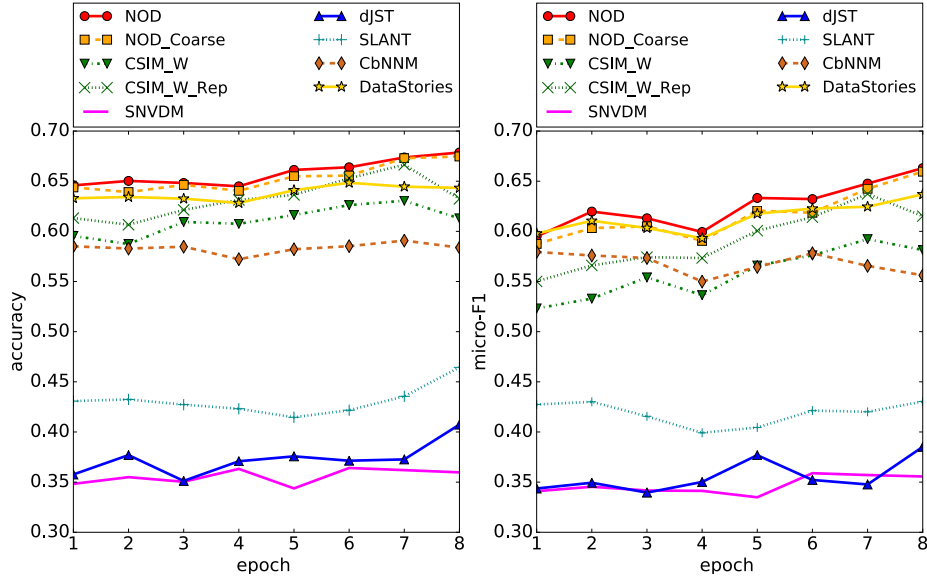

Figure 4: Accuracy and micro-F1 versus epochs on BREXIT.

We report in Figure 4 the accuracy and micro-F1 of our method against baselines over epochs on BREXIT. It can be observed that supervised models generally outperform unsupervised or weakly-supervised models. In addition, we observe an upward trend for dynamic models owing to their ability in capturing historical context in the previous epochs. Static models such as SNVDM and CbNNM give more constant results as they only have the access to a fix amount of training data in each epoch. We also observe that CSIM\_W was beaten by CSIM\_W\_Rep which represents each tweet by word embeddings in-

stead of bag-of-opinion-words. DataStories outperforms all the other baselines. Nevertheless, our proposed NOD and NOD.Coarse perform similarly and they both give superior results compared to DataStories in general across all the epochs.

#### 360 4.2.2. Election

Figure 5: Accuracy and micro-F1 versus epochs on ELECTION.

Figure 5 presents the accuracy and micro-F1 versus epochs on ELECTION. Again, we observe that supervised models are superior to unsupervised or weakly-supervised models. Static models exhibit drastic fluctuations over epochs. It is more noticeable for DataStories that it gives a significant drop at Epoch 6. This may partly due to the mismatch of the training data in the neighboring epochs. SNVDM and CbNNM are relatively steady compared to DataStories since they captured context information to some extent. Conversely, dynamic models give more consistent results across epochs. NOD slightly outperforms NOD.Coarse and they beat all the other baselines across all epochs except for epoch 6, where CSIM.W produced comparable results. Nevertheless, CSIM.W is inferior to NOD overall.

Table 4: Wilcoxon  $T$  test statistics of the Wilcoxon signed-rank test on the classification accuracy ( $T_{acc.}$ ) and recall ( $T_{rec.}$ ) between NOD and the top 3 baselines, respectively.

Baselines	BREXIT		ELECTION	
	$T_{acc.}$	$T_{rec.}$	$T_{acc.}$	$T_{rec.}$
CSIM_W	0.004	0.004	0.003	0.003
CSIM_W_Rep	0.008	0.008	0.003	0.003
DataStories	0.010	0.016	0.001	0.001

#### 4.2.3. Statistical Significance Test

We notice in Figure 4 that the gaps between NOD and two baselines, CSIM\_W\_rep and DataStories, are small at some points. To further verify that the proposed  
 375 model significantly outperforms the baseline approaches, we measure the statistical significance between NOD and the 3 top-performing baselines. Some past research suggested using Wilcoxon signed-rank test rather than paired  $t$ -test for the prediction over time series data (Mozetič et al., 2018; Oliveira et al., 2016). Following the sequential validation setup in (Mozetič et al., 2018), we posit that  
 380 models trained by a training set are used to predict the user-level stance in the subsequent epoch, which is in line with our original experimental setup. The null hypothesis is that the differences between NOD and a baseline follow a symmetric distribution around zero. The significance threshold is chosen as 5% in accordance with (Oliveira et al., 2016). We report the statistics in Table 4.  
 385 It shows that all the test statistics  $T$  fall into the rejection region. Therefore, we accept the alternative hypothesis that the proposed model outperforms the baseline approaches, which is at the 1% significance level on ELECTION. When evaluated by recall on BREXIT, NOD exceeds Datastories at the 5% level.

#### 4.2.4. Analysis of Errors

390 We further analysed the wrongly predicted instances and found that these users typically have insufficient neighborhood context for the model to make correct prediction. For example, a user did not post any tweets before and was only linked to the author of the tweet “BBC debate well said. Brexit, take back

control, vote leave”. With such limited neighborhood context information, our  
 395 model predicted that the user’s stance is to ‘support’ Brexit. However, this  
 user then posted a tweet “I will be voting remain. But I am not calling myself  
 a remainder.” in the next epoch showing the opposite stance. Due to the  
 training setup of our model (trained on a user’s previously posted tweets and  
 their neighborhood context and to predict the user’s stance in the next epoch  
 400 without seeing their future posted tweets), there is no way for our model to  
 make correct prediction in such cases.

#### 4.2.5. Impact of Contextual Attention

We studied the effect of contextual attention by either excluding the topical  
 attention or ignoring neighborhood context. More concretely, we set  $\alpha_1$  to  
 405 0 so that the topical attention is not accounted for. We also examined the  
 effect of ignoring neighborhood tweets by tying up  $\beta_{1:N}$  to 0. We tested these  
 settings on the last epoch for both datasets and show the results in Table 5.  
 It can be observed that neighborhood attention boosts the performance more  
 significantly while topical attention also helps increase the accuracy. This shows  
 410 that both topics and neighborhood context are indeed important for user-level  
 stance prediction.

We argue that the neighborhood attention helps boosting the performance  
 because of *homophily* (McPherson et al., 2001). But we also acknowledge that a  
 user’s stance could be totally different from most of their friends’. That is why  
 415 our model simultaneously takes into account both the user’s previous tweets  
 and their neighborhood context and learns attention weights automatically in  
 order to achieve an optimal decision for the user-level stance prediction. In our  
 future work, we will explore a more principled way to study the major factors  
 influencing the opinion formation.

#### 4.2.6. Tracking Stance Dynamics

To demonstrate that our model is able to track stance dynamically in a sen-  
 sible way, we carried out detailed studies on three example topics, ‘Economy’,

Table 5: User-level stance prediction accuracy on the last epoch with or without contextual information.

	BREXIT	ELECTION
Original	<b>0.6786</b>	<b>0.6865</b>
–Topics	0.6679	0.6794
–Neighbor Context	0.6451	0.6592

‘*Boris&Farage*’ and ‘*Immigration*’, from BREXIT and displayed their stance transition over epochs. To obtain the overall topic-stance, we first aggregated  
425 by all users the stance distributions of a particular topic, normalized the aggregated scores and finally calculated the weighed sum as the overall stance score towards the topic. Here, we assigned weights -1, 0 and 1 to opposed, neutral and supportive stance respectively. For the user-level topic-stance, we calculated the final stance score in a similar manner.

Figure 6: Global topic-stance and user-level topic-stance on BREXIT.

430 Figure 6 shows the overall stance and example user stance towards these three topics. We can observe that the overall stance for ‘*Economy*’ is more towards opposing, indicating that people generally felt that Brexit would affect economy negatively. The overall stance for ‘*Immigration*’ is however positive

with more people switched to the positive view towards the end of Epoch 8.

435 This shows that more people thought Brexit would be good to control the immigration. As for ‘*Boris&Farage*’, the overall stance slightly fluctuates around neutral. For the user-level topic stance, User-A changed her views more drastically. She started with negatively views on all these three topics, but eventually switched to positive views at Epoch 8.

440 Another ability of our model is to infer a users’ stance even if they posted no tweets in the current epoch. This is achieved by artificially arranging NULL tweets for them while their neighborhood contexts are designed as contexts of the user at several time points in the current epoch. As illustrated in Fig. 6, User-A did not post any tweets in Epoch 6. Nevertheless, our model was still  
445 able to predict her stance (marked with crosses). The prediction results were actually consistent with the stances revealed in User-A’s tweets in Epoch 7. One of her tweets in Epoch 7 is “*The eu immigration policy will definitely crash the UK economy, taking us all with it. How many from turkey?#Brexit*”, indicating that she was worried about the immigration and wanted a Brexit.

#### 450 4.2.7. Comparison With a Two-Class Problem Setting

Some previous studies found that determining neutrality is difficult on social media data (Tan et al., 2011; Hu et al., 2013; Zhu et al., 2019). They thus confined their models to a two-polarity setup. To further confirm the effectiveness of the proposed model, we also delve into the two-class scenario, where the neutral  
455 tweets have been discarded. Since HLDA is an unsupervised non-parametric model, we retain the same topic embeddings that were used in the three-class setting for NOD. Other configurations remain the same. Figure 7 plots the two-class classification accuracy of different methods on both datasets. Compared with the results in Figure 4, we can observe improved results for the supervised  
460 methods and worse results for the LDA-based approaches, though the overall trend across epochs did not change much, especially on the ELECTION dataset, owing to its relatively small number of neutral tweets. Our proposed NOD and NOD\_Coarse still outperform all the other models consistently across all the

Figure 7: Two-class classification accuracy on BREXIT and ELECTION.

epochs on both datasets.

## 5. Conclusions and Future Work

In this paper, we have proposed the Neural Opinion Dynamics (NOD) model which can effectively take into account tweet content, topical and neighborhood context for user-level stance prediction. In particular we model a user with a sequence of posts, each of which embodies the user’s own tweet. On this basis, we propose an attention mechanism to better integrate the self content and social context information. Finally, we employ an RNN on the time series to model user behaviors. Compared with static models which perform one-time prediction, our model can dynamically track topic-dependent stances. Experiment results on the two Twitter datasets verified the feasibility of NOD, showing that both the context attention and the dynamic setup help improve stance classification results.

In the future, we would like to explore following three directions. First, besides the neighborhood information derived from the following-follower relations, it is possible to construct the social networks using the *re-tweeting* or *mentioning* relations. However, such social networks might be more sparse and methods  
480 need to be investigated to tackle the sparsity problem. Second, in our current approach, only a fixed number of neighborhood tweets are used to form the neighborhood context. It is possible to also take into account each neighbor’s social influence score since opinions from more influential users should carry  
485 higher weight. Last, NOD assumed that topic information is obtained beforehand. In future work we could investigate a unified model for joint topic-stance detection over streaming data.
